ABSTRACT
Parallel software codes in high performance computing (HPC) continue to grow in complexity and scale as we enter the exascale era. A diverse set of emerging hardware and programming paradigms make developing, optimizing, and maintaining parallel software burdensome for developers. One way to alleviate some of these burdens is with automated development and analysis tools. Such tools can perform complex and/or remedial tasks for developers that increase their productivity and decrease the chance for error. So far, such tools for code development and performance analysis have been limited in the complexity of tasks they can perform. However, with recent advancements in language modeling, and the wealth of code related data that is now available online, these tools have started to utilize predictive language models to automate more complex tasks. In this paper, we show how large language models (LLMs) can be applied to tasks specific to high performance and scientific codes. We train LLMs using code and performance data that is specific to parallel codes. We compare several recent LLMs on HPC related tasks and introduce a new model, HPC-Coder, trained on parallel code. In our experiments we show that this model can auto-complete HPC functions where general models cannot, decorate for loops with OpenMP pragmas, and model performance changes in two scientific application repositories.

1 INTRODUCTION
In recent years, large language models (LLMs) have become the state of the art in many language modeling related tasks. Their ability to model token probabilities within a sequential context make them desirable for language tasks such as text generation and sequence classification. In addition to being used for natural language, such models have recently been applied to many programming language related tasks. The predictive capabilities of these models translate well to coding tasks, and the wealth of source code available online provides significant data for training large models.

LLMs trained on source code data have been utilized to automate numerous software development tasks such as code completion, malware detection, code refactoring, etc. Additionally, they have been able to automate tasks previously considered impossible to automate such as code summarization and generation using natural language. Training LLMs for these tasks requires significant amounts of source code data that is fortunately available online from open-source code repositories on GitHub, gitlab etc. However, this data requirement for training LLMs is prohibitive for tasks where such data may not exist. One such task is that of modeling performance (execution time) based on source code.

Performance data for arbitrary code is difficult to obtain at scale with large numbers of samples. First and foremost, it is non-trivial to automate the collection of performance data for arbitrary source code. The code needs to be built and run in order to measure performance, and this process can vary significantly across repositories. This can be particularly difficult for production scientific codes due to code complexity and dependence on external libraries. Second, performance depends on numerous variables besides just the code such as input problem, architecture, and current machine load/congestion. These either need to be fixed in the dataset or accounted for within the end modeling problem. Finally, source code needs to be considered holistically when modeling performance, since minor changes in one place may drastically impact performance elsewhere. For example, changing the data layout within a data structure will impact the performance of data access where that structure is used. This means the entirety of the source code needs to be included in the dataset and performance needs to be collected at a finer granularity.

When a lack of data becomes a hurdle in machine learning tasks it is typically solved through data augmentation and/or transfer learning. Data augmentation involves extending and/or duplicating data in a manner that still preserves meaning and representational capacity. Transfer learning is done by first training a model on a related or simpler task and then transferring that knowledge to a new problem requiring fewer samples to learn. We can employ transfer learning here by using LLMs that have learned to model source code and then transferring that knowledge to then learn how to model performance of source code using fewer samples.

In this paper we utilize an LLM to model HPC and scientific related source code and then apply that to the problem of performance modeling. We first demonstrate how our trained model, HPC-Coder, outperforms other LLMs on HPC specific tasks such as code generation and OpenMP pragma labeling. A set of code generation tests specific to HPC are introduced and the model can pass these at up to an 53% higher rate than the other models. Additionally, it is able to
When applying machine learning to textual data we need a model. We demonstrate how the model can predict relative performance of source code changes with up to 88% accuracy. In summary, this paper makes the following contributions:

- We present an LLM, HPC-Coder, tuned to model HPC and scientific code. We show that it trains to better language modeling scores over HPC related code than other state-of-the-art models.
- We introduce a set of HPC code generation tasks and demonstrate that our model completes these tasks at a significantly better rate than other models on HPC-specific code.
- We demonstrate how our model can be used to predict OpenMP pragmas with 97% accuracy.
- We utilize our model to predict relative performance of source code changes.

## 2 BACKGROUND

This section provides background on transformer-based language models and how they can be applied to source code data.

### 2.1 Large Language Models

When applying machine learning to textual data we need a model that takes text as input and, through the process of training on previous data, learns how to predict some property of that text. In recent years such models have been mostly dominated by large transformer-based models. Transformers were first introduced by Vaswani et al. [32]. They are designed to work with sequential data unlike recurrent and long short-term memory neural networks. However, they differ in their use of a self-attention mechanism to attribute importance weights to inputs into the model. Due to this mechanism transformers also process entire sequences at once unlike recurrent neural networks.

These self-attention units make up the basis of transformer networks. Weights are divided into query, key, and value weights (namely $W_Q$, $W_K$, $W_V$). These are multiplied by each input token and stacked to form the matrices $Q$, $K$, and $V$, respectively. Given these matrices and the dimensions of the key vectors $d_k$, the attention can be computed as shown below.

$$
\text{Attention}(Q, K, V) = \text{softmax} \left( \frac{QK^T}{\sqrt{d_k}} \right) V
$$

These weight matrices form a single attention head. Typically transformers employ several attention heads to form a multi-attention head layer. Having multiple attention heads allows each of them to learn, or attend to, different abstractions in the input, such as parts-of-speech for natural language input.

Generally these networks are trained to model the conditional probability of observing a language token or a sequence of tokens. For instance, given a string of observed tokens $t_1, t_2, \ldots, t_{i-1}$ we may want to find the most likely next token $t_i$.

$$
t_i = \arg \max_{t \in \mathcal{T}} P(t_i = t \mid t_1, t_2, \ldots, t_{i-1})
$$

Similarly we may want to know the probability of a sequence of tokens occurring given the entire observed dataset $P(t_1, t_2, \ldots, t_N)$ (i.e. how likely is a given English sentence to be real given my previous knowledge of the language). Using this probability we can define a metric called perplexity.

$$
\text{Perplexity}(T) = \left( \frac{1}{P(t_1, t_2, \ldots, t_N)} \right)^{\frac{1}{N}}
$$

With this metric a model that scores a lower perplexity on its test set $T$ is better as it assigns a higher probability to the test data. The ratio is normalized to be invariant to the size of the test set. Rewriting the formula for perplexity we can see that it is equivalent to the exponential of the cross-entropy.

$$
\text{Perplexity}(T) = (P(t_1, t_2, \ldots, t_N))^{-\frac{1}{N}}
= \exp \left( -\frac{1}{N} \log P(t_1, t_2, \ldots, t_N) \right)
$$

This allows us to train the language model with cross-entropy loss. Minimizing the loss will, in turn, minimize the perplexity. The perplexity is recovered by simply taking the exponential of the loss. It is important to note that perplexity measures model confidence and not accuracy. However, it has been demonstrated empirically that lower perplexity generally leads to better performance on downstream tasks.

### 2.2 Text Generation

Once a model is trained it can be used to generate new text given some context. Since the LLM models token probability it may seem simple to select the most probable next token, however, this can lead to poor text generation. Often a model’s attention puts more focus on the most recent tokens causing this selection method to get stuck in loops or suddenly forget context. Most recent works combat this issue by sampling from the model’s distribution, but there are several important caveats when doing this. For instance, we want to avoid sampling from the tail as this could dramatically throw off further tokens sampled. Here we discuss several of the sampling methods used later in this paper such as temperature, top-$k$, and nucleus sampling.

**Temperature**. When sampling temperature controls how confident the model is in the sampled token. Lower temperature leads the model to assign more confidence in the most likely tokens in the distribution. On the other end, the model will more uniformly assign confidence across the distribution when the temperature is higher. This term comes from statistical thermodynamics where lower energy states are more frequent with a higher temperature.

Temperature is incorporated by dividing the logits by the temperature, $\text{temp}$, before computing the softmax output. The logits are the raw, un-normalized outputs of the model and the softmax is used to turn this vector into probabilities.

$$
\text{softmax} \left( \frac{\text{logits}}{\text{temp}} \right)
$$

Thus, as $\text{temp} \rightarrow 0$ the output becomes the argmax and as $\text{temp} \rightarrow \infty$ it leads to a uniform sampling.
Top-k Sampling. In top-k sampling the most likely k tokens are sampled from the model. This aims to exclude the distribution’s tail and prevent the model from rapidly getting off-topic. However, this can also reduce the quality of predictions if the body of the distribution is wider than k. A common choice for k is 50.

Nucleus Sampling. Nucleus, or top-p, sampling aims to solve the shortcomings of top-k sampling by choosing a more meaningful cut-off point. In this method the CDF of the distribution is computed and sampling is cut-off when the CDF exceeds p. A common choice for p is 0.9.

2.3 Applying LLMs to Code

LLMs can be trained on a variety of downstream tasks and objectives. When applied to source code data they are typically trained as left-to-right, masked, or encoder-decoder models.

Left-to-Right. Left-to-right or causal language models are trained to predict the most probable next token in a sequence. The model receives and generates text in a left-to-right fashion, which is where it gets its name. This limits the amount of context the model can see as it cannot use later tokens in its prediction even if they are present in the data. Left-to-right models are useful for text generation related tasks.

Masked. Unlike left-to-right models, masked models can predict the most probable token for any position in the text. After removing random tokens in the samples and replacing them with mask tokens, the model is trained to predict the most probable tokens to replace the masks with. In this configuration masked models can make use of more context in their predictions.

Encoder-Decoder. Another common approach is to train a left-to-right model to decode a sequence after it has been passed through an encoder. This type of model can be combined with several different objectives and is often used with sequence-to-sequence prediction.

To apply left-to-right models, which are focused on in this paper, to source code you simply need to provide the model with prior context as a sequence of tokens and then let it generate new tokens until some stopping threshold. The prior context is typically a natural language comment followed by a function declaration.

4 DATA GATHERING AND PRE-PROCESSING

In order to train a large language model to understand and generate HPC source code we need to show it lots of examples. To accomplish this we must first build a data set for training. In this section we detail our collected dataset and how it is processed.

4.1 HPC Source Code Data

To train the model on HPC and scientific code we first collect a sufficiently large dataset of source code. The HPC source dataset is collected from GitHub repositories. The source files are pulled from repositories with C/C++ marked as the primary language and with \( \geq 3 \) stars. The repositories are additionally filtered by HPC related GitHub topics. Once cloned, we collect all the C/C++ source files based on their file extension.

This dataset is collected and structured in the same manner as the C/C++ source dataset from Xu et al. [34]. Their dataset is scraped from GitHub in a similar manner with the exception of only including repositories with \( \geq 5 \) stars.
Figure 2 shows the distribution of lines of code (LOC) by file types in the HPC source dataset. There are roughly the same number of LOC in both .c and .cpp files. The distribution of actual file counts follows the same trend.

4.2 Data Pre-processing

Allamanis [5] shows how duplicate source data, which is prevalent across GitHub repositories, can adversely bias LLMs during training. To prevent this we filter our datasets by removing duplicate files based on the hash of their contents. We use sha256 to hash the contents of the file.

In addition to deduplicating we also filter out small and large files. Source files larger than 1 MB are designated as large files and removed. These are generally entire libraries in a single source file or contain raw data within the code. Additionally, files containing less than 15 tokens, as defined by the language vocab, are not included. The reduced dataset sizes after deduplication and filtering are listed in Table 1. Approximately 18% of the files are removed during this processing. Table 1 shows the properties of the data set after each step of deduplication and filtering.

<table>
<thead>
<tr>

</tr>
<tr>
<td>Deduplicate + remove small/large files</td>
<td>196,140</td>
<td>50,017,351</td>
<td>1.62</td>
</tr>
</tbody>
</table>

After filtering source files we tokenize the dataset to obtain integer values for the text that can be used as input into the model. We use the pre-trained tokenizers for each of our selected models (see Section 5). These are all GPT-2 [28] based Byte-Pair Encoding (BPE) tokenizers. Using these tokenizers we generate tokenized versions of our dataset.

5 FINE-TUNING METHODOLOGY

In this section, we describe the models used and how they were selected. We further discuss the methods used to fine-tune them on our collected dataset.

5.1 Models Selected For Fine-Tuning

Recent years have seen the introduction of a significant number of large language models. These models can range in size from 100 million to more than 100 billion parameters. Such large models have been shown to work well for language modeling, but pose significant hurdles to train and use in practice. They can take months to train on large GPU clusters and typically cannot feasibly run inference on consumer-grade hardware. Thus, choosing the right model requires selecting one that can sufficiently model the language data, but also be reasonably deployed for downstream tasks.

Keeping the above mentioned requirements in mind, we select several models for fine-tuning and/or testing. These are listed in Table 2. All of these are based on GPT-2 [28] and/or GPT-3 [10] architectures with slight variations in size, configuration, and pre-training data. GPT-2, the smallest in our experiments, is pre-trained on the WebText [18] dataset, which is a collection of language data scraped from the internet. We use the 1.5 billion parameter GPT-2 Medium model variant in this paper. PolyCoder [34] is pre-trained on a collection of solely source code data from GitHub that contains a mixture of 12 popular programming languages [34]. Between these two is GPT-Neo [9] that is pre-trained on the Pile dataset [16]. This dataset contains a collection of approximately 800GB of text data from the internet, academic articles, source code, etc. Most notably this dataset has a mixture of natural language and code. It has been demonstrated that pre-training over both natural language and code can improve the performance of the model in downstream code related tasks [34].

</tbody>
</table>

Notably, we exclude models such as Codex [11], the state-of-the-art model that powers GitHub CoPilot, from our experiments due to the model and its dataset being closed source. It is currently only accessible for inference via a non-free API. Codex’s dataset being closed source is significant as we cannot remove data it has trained on from the dataset we use to evaluate its performance, so its results would be overly optimistic. This prevents a realistic evaluation and comparison.
5.2 Fine-Tuning
To train our model we rely on much of the functionality provided in the HuggingFace [1] Python library. This library automates many of the tasks related to loading, preprocessing, and running language models on datasets. In particular, we use the Trainer interface with DeepSpeed [26] as the backend to optimize training. DeepSpeed is a recent framework that provides distributed training functionality and several memory optimizations to enable large models to fit in GPU memory.

Starting with the pre-trained models we fine-tune them on a single node with an AMD EPYC 7763 CPU, 512 GB memory, and four 40 GB NVIDIA A100 GPUs. With ZeRO memory optimizations [29], all of the models fit entirely within a single A100 and are, thus, trained using pure data parallelism. We refer the reader to [8, 27] for a comprehensive overview of training deep neural networks in parallel.

For all models the AdamW [25] optimizer is used to update model weights and minimize the loss. We set the learning rate to $5 \times 10^{-5}$ and Adam parameters $\beta_1$ and $\beta_2$ to 0.9 and 0.999, respectively. These hyperparameters are consistent with typical values in the literature. 16-bit floating point precision is used to accelerate training and reduce model size on the A100s.

During fine-tuning we record the perplexity of the model on the training data. This is calculated as the exponential of the training loss (see Section 2.1). Every 1000 optimizer steps we also run the model over the validation dataset and record the perplexity and accuracy at predicting tokens. The validation dataset is 5% of the full dataset that is separate from the training dataset.

6 DOWNSTREAM INFERENCE TASKS AND EVALUATION METRICS
In this section we introduce the tests and metrics used to evaluate the performance of the language models.

6.1 Code Completion
A standard benchmark for code generation tasks is the HumanEval benchmark [12]. This is comprised of 164 sample Python problems, where the input to the model is a natural language description of a function and function header. The model generates code for the function and is scored on functional correctness rather than textual similarity or equivalence.

We introduce our own adaptation of this benchmark for HPC C/C++ programs. The model is tested against 25 custom HPC code generation problems including simple numerics, OpenMP parallel code, and MPI routines. Table 3 lists the tests used in our evaluation. Figure 3 shows a sample prompt (white background) and output (blue background) for a shared-memory parallel implementation of saxpy. The prompt (white) is shown to the model and it is expected to generate text functionally equivalent to the text in blue.

For each prompt we generate $N$ samples of the code, compile/run the samples, and record the number that are functionally correct. For a particular prompt $p$ we can use the number of generated samples that are correct, $c_p$, out of the $N_p$ total samples generated to approximate the pass rate given $k$ samples, or pass@$k$, as

$$\text{pass}@k = 1 - \left( \frac{N_p - c_p}{N_p} \right)^k$$

(1)

For each model we report average pass@$k$ as the average pass rate over all the prompts $1 \ldots P$ as shown below.

$$\text{average pass}@k = \frac{1}{P} \sum_{i=1}^{P} \left[ 1 - \left( \frac{N_i - c_i}{N_i} \right)^k \right]$$

(2)

This metric provides insight into the rate at which a model can generate functionally correct code. In our experiments we calculate the pass@$k$ score for several temperatures, namely 0.1, 0.2, 0.4, 0.6, and 0.8, and select the best one. This is in line with experiments in related literature [34]. For each temperature and test we generate $N = 100$ samples. The code is generated with nucleus sampling using $p = 0.93$. 

Table 3: Code generation tests. Sequential, OpenMP, and MPI denote whether the test includes a version with that parallel backend.

Figure 3: An example prompt asking the model to generate a parallel version of saxpy. The comment and function header make up the prompt. The function body highlighted in blue shows a potential model output.
To compile the generated code we use `g++` with the `-O2 -std=c++17 -fopenmp` flags. For tests that need MPI we use the OpenMPI `mpicxx` compiler. If the build is successful, then a corresponding driver binary is called that will call and test the generated function for correctness. For tests that require OpenMP or MPI we only denote them as correct if they used the corresponding parallel framework to compute their result.

### 6.2 Predicting OpenMP Pragmas

A common HPC coding task is decorating for loops with OpenMP pragmas. Every pragma starts with `#pragma omp parallel` and is followed by a list of optional clauses that modify the behavior of the parallel for. To test the model’s understanding of this common HPC paradigm by having it write OpenMP pragmas for arbitrary for loops.

To fine-tune the model for this task we create a dataset of every for loop with an OpenMP pragma from our HPC code dataset. 500 tokens of context from before the for loop are also included. This results in a dataset with 13,900 samples.

Since our model is left-to-right we format each sample by moving the pragma to directly after the for loop and a unique separating token `<begin-omp>`. This allows us to use the model by providing a for loop plus some context and the model will generate an OpenMP pragma to decorate the for loop.

Each model is trained on this smaller dataset for 3 epochs (passes over the entire dataset). To prevent overfitting we use a starting learning rate of $3 \times 10^{-5}$. During training 10% of the dataset is set aside for validation.

To measure the success of this test we use the accuracy of generating correct pragmas. For this problem we define a correct pragma in two ways: syntactic and functional. To measure syntactic correctness we compare the generated pragma with the actual pragma for textual equivalence. Since we cannot run arbitrary loops from our dataset we measure functional correctness by comparing the generated pragmas with the actual ones while ignoring differences that do not contribute to functionality. For instance we ignore reordering of variables and clauses where these do not matter. Additionally, clauses such as `schedule` are ignored. We record accuracy from both of these correctness metrics for each model.

### 6.3 Relative Performance Prediction

In addition to text generation we can also use the LLMs for classification. Here we use them to predict performance slowdowns in version control history. To accomplish this we give the model text for a region of code before and after a Git commit. The codes are concatenated with a unique token separating them, namely `<COMMIT>`. With this data the model is trained to predict whether the second code will be slower (positive) or the same/faster (negative). To get this data we run each commit for the Kripke [22] and Laghos [14] applications. These are small HPC apps meant to mimic the computational behavior of larger scientific applications. We automate building and running each commit to the best of our ability and collect performance results for 830 commits in total.

We then train the model on 90% of this data with the other 10% set aside for evaluation. The model takes the concatenated sequences of code before and after commits as inputs and is trained for the binary classification problem of predicting relative performance. The training objective is classification accuracy, which we also use to measure success for this task.

### 7 RESULTS

In this section we present the training and evaluation results from the methodology discussed in Section 6.

#### 7.1 Fine-Tuning on HPC Data

Figure 4 shows the training and validation perplexity during fine-tuning. Here perplexity is calculated as the exponential of the loss as described in Section 2. Each model converges to a low perplexity score over the separate testing set (between 2 and 4).

GPT-Neo and PolyCoder achieve comparable scores (within 0.01) and GPT2-Medium scores a higher perplexity. All three have different pre-training data sets and the former two are of a larger size than GPT2-Medium (see Table 2). From this we can conclude that for this problem the pre-training dataset had less of an impact on validation perplexity than the model size. The higher perplexity of the larger models means that they are modeling the language better.

![Figure 4: Training results on the HPC source code dataset. Lower perplexity is better. GPT-Neo and PolyCoder converge to comparable perplexities over the validation set. GPT2-Medium, the smaller model, converges to a higher, but still good perplexity.](image)

Furthermore, we test the performance on text generation during training. This is to find if there is a point where the model starts overfitting the data, since LLMs are subject to catastrophic forgetting during fine-tuning. Catastrophic forgetting is the phenomenon where previously learned information is lost or forgotten as the model continues training and updating its weights. It is typically prevented by minimizing the amount of fine-tuning and using a sufficiently low learning rate.

Figure 5 presents the results from our evaluation tests during training on the PolyCoder model. After seeing about 50,000 samples during training the model starts to decrease in evaluation performance. This is in contrast to the perplexity which keeps improving past 50,000 samples. Based on this result we stop training at 50,000 samples and use these weights for the rest of the evaluations. Additionally, due to the computation time needed to run this test we use the 50,000 samples stopping point for training in all the models.
For the rest of the results presented in this section we will use PolyCoder+HPC, GPT-Neo+HPC, and GPT2+HPC to refer to the respective models after fine-tuning on the HPC dataset.

Figure 5: Downstream evaluation performance across training iterations for PolyCoder+HPC. The models start to perform worse around 50,000 samples even though the perplexity keeps improving.

7.2 Code Completion
Here we present the results from the text generation tests described in Section 6.1. Figure 6 shows the average pass@k rates for the code generation tests. The pass@k values are computed according to Equation 2. We use PolyCoder as a baseline for comparison since it is a state-of-the-art LLM for code generation. PolyCoder+HPC scores the best for average pass@1, pass@10, and pass@100. For each value of $k$ the models score in the order of PolyCoder+HPC, PolyCoder, GPT-Neo+HPC, and GPT2+HPC. PolyCoder+HPC gains the slight edge over the original PolyCoder by successfully generating code for the HPC-specific tasks (see Figure 7).

In Figure 6 we see that GPT2+HPC scores significantly lower than the other models. This is likely due to the smaller model size and the fact that there is no source code in its pre-training dataset. In this instance fine-tuning is not enough to enable GPT2 to generate correct C++ HPC code.

 Altogether, the scores are indicative that the model has learned how to generate valid C++ code. For instance, if the best model, PolyCoder+HPC, is permitted to generate 100 samples, then 71% of them are correct on average across all the tests. Similarly for 1 sample generated this is 25%. These numbers roughly align with results from [34] on the HumanEval Python tests. However, the results are not directly comparable since they are a different set of tests in a different programming language.

To demonstrate the generative capabilities of the specialized models we reduce the code generation tasks to those that are specific to HPC. This includes code that uses OpenMP and/or MPI parallelism. Figure 7 shows the performance when restricted to these tests. We see that PolyCoder is unable to generate OpenMP and MPI code as it scores significantly lower than the rest. GPT2+HPC still performs fairly low, however, its score has actually improved slightly over Figure 6. This is due to the fact that it has only seen HPC-specific code during training and that is exclusively what is being tested here.

Figure 6: Comparison of models on code generation. The clusters represent the average pass@k scores for $k = 1, 10$ and 100. Higher percentage is better.

Another point of interest besides functional correctness is syntactic correctness. This can be measured by the total number of generated samples that compile successfully. This is how often the model generates valid code, whether it is functionally correct or not. For our tests this data is presented in Figure 8. PolyCoder and PolyCoder+HPC both perform the best compared to the other models with 84% and 86% of samples compiling correctly, respectively.

Figure 7: Comparison of models on code generation for HPC-specific functions. The clusters represent the average pass@k scores for $k = 1, 10$ and 100. Higher percentage is better.

Figure 8: Comparison of models on code generation for HPC-specific functions. The clusters represent the average pass@k scores for $k = 1, 10$ and 100. Higher percentage is better.
GPT-Neo+HPC performs slightly worse at 74% and GPT2-HPC has only 30% of samples compile. The worse performance of the latter two can likely be attributed to their pre-training datasets having less code in them. We can also observe that for all models there is a visual correlation between build and correctness rates, which is expected since a model needs to compile in order to be functionally correct.

Figure 8: Comparison of the models’ build rate. Both PolyCoder and PolyCoder+HPC have the best percentage of total samples that successfully compile. Higher percentage is better.

The code in Figure 9 shows example output from PolyCoder and PolyCoder+HPC on generating OpenMP code to compute a sum in parallel. We see that PolyCoder is able to produce correct sequential code, however, it fails to add any OpenMP pragmas. The PolyCoder+HPC model is able to correctly tag the for loop with an OpenMP pragma.

A similar example with distributed memory is shown in Figure 10. The PolyCoder+HPC is able to generate correct MPI code to compute an average in parallel across ranks. PolyCoder often generated long and incorrect code that demonstrated little understanding of how to write MPI routines. The example presented is indicative of the rest of the MPI samples generated by PolyCoder. Notably, some instances did contain MPI calls, so PolyCoder must have some MPI code in its pre-training dataset. However, it lacked the ability to properly use those MPI calls.

Since PolyCoder+HPC scores the highest in training and these code generation tests we select it for further comparisons in the rest of the paper. We continue to use PolyCoder as a baseline.

7.3 Predicting OpenMP Pragmas

Figure 11 shows the results from the OpenMP experiments detailed in Section 6.2. We see that both models are able to generate functionally correct OpenMP pragmas with high accuracy. PolyCoder+HPC is able to do this with 97% accuracy and PolyCoder 94%. The LLMs are exemplary at understanding the dependencies of the for-loop and what clauses are required to correctly parallelize them. We see that the model that has seen lots of OpenMP code before does a better job at generating pragmas.

We can also look at how well the models reproduce the pragmas exactly. This means all the clauses and variables within those clauses are in the same order in the dataset and in the output from the model. These results are shown in the blue bars in Figure 11. While less meaningful than functional correctness, it is interesting that the model is able to exactly reproduce pragmas it has not seen before with relatively high accuracy (67% and 61%). This is likely due to certain trends in the construction and ordering of OpenMP clauses that the LLMs are learning as they train.

7.4 Relative Performance Prediction

Figure 12 shows the results from the relative performance prediction tests (see Section 6.3). Both models achieve high classification accuracy with PolyCoder+HPC being slightly better at 88% and PolyCoder at 86%. This means that for 88% of the code changes in the two repositories version control history PolyCoder+HPC is able to correctly identify if there will be a performance slowdown. The success of this test demonstrates that the models are able to correlate their prior language understanding with performance related properties of code. This means we can leverage LLMs and fine-tuning to model code performance without the need to collect large amounts data.

8 RELATED WORK

In this section we detail related work that uses LLMs to study source code and work that uses machine learning to model the performance of source code.
8.1 Applying LLMs to Code

With the explosion in research in transformer models and LLMs there have been a large number of papers applying these techniques to source code. Most of these methods have extended GPT-2 [28], GPT-3 [10], or BERT [13, 24] models and trained them on code. A notable instance is Codex [11], which is a modification of GPT-3 that is targeted for source code generation. While it appears to be state-of-the-art in code generation, its architecture, weights, and training data are all closed source and only inference is available via a paid API.

A large amount of this recent research has focused on code generation. These usually take a mix of code and natural language and learn how to meaningfully finish the code. While seminal works have continued to improve code generation with better and bigger models [10, 11, 24], other works have explored how to better utilize these tools in software engineering workflows [7, 15, 31]. Some flip code generation around and learn to generate natural language code summaries from code snippets [3, 4, 19, 20].

These models can even be trained for tasks such bug and malware detection [21, 30]. LLMs can also be used to suggest fixes in these cases rather than just identify problematic code. Many other previously difficult to automate software development tasks have since been tackled by applying LLMs [2].

8.2 Machine Learning Applied to Source Code Performance

However, one important problem in software development that has not received much research with LLMs is that of performance. Many of the reasons listed in Section 1 have prevented meaningful studies from being accomplished. Previously approaches used code2vec [6], ir2vec [33], or a similar method to first map source
were successfully used for some performance related analytical innovations into practical tools that can be easily used by optimal code. Additionally, we plan to investigate how to engineer how to tune the model to generate not just correct, but performance accomplished using our language model. 9 CONCLUSION AND FUTURE WORK

In this paper we have demonstrated how a LLM can be fine-tuned
HPC code and outperform other LLMs in HPC related tasks such
as HPC code generation and performance modeling. We have ac-
complished this by training a model that can generate functionally
correct HPC code at up to a 53% higher pass rate and can accurately label for loops with OpenMP pragmas with 97% success. Additionally, we have further demonstrated how this trained model can be utilized to study performance properties of source code with little data. These results demonstrate the need for and usefulness of HPC specialized language models. This best model, PolyCoder-HPC, we present as HPC-Coder.

In future works we will explore further analyses that can be accomplished using our language model. We also plan on exploring how to tune the model to generate not just correct, but performance optimal code. Additionally, we plan to investigate how to engineer these innovations into practical tools that can be easily used by scientific and HPC developers to enable them to produce better code more efficiently.
